Abstract

The suitability of six concrete mixtures for use in direct containment of liquefied natural gas (LNG) was assessed using nuclear magnetic resonance (NMR), x-ray computed tomography (XRCT) and acoustic emission (AE). The mixtures were prepared with river sand as fine aggregate using different coarse aggregates. The mixtures were cooled from ambient to cryogenic temperatures at a cooling rate of 3°C/min. Proton NMR measurements and XRCT imaging were carried out before and after cooling to monitor changes in porosity and pore size distribution, and internal microstructure, respectively. AE sensors monitored damage evolution during cooling and warming. NMR results indicated porosity increases of 0%, 0.3%, 1.4% and 3.3% in the non-air-entrained trap rock aggregate, limestone aggregate, sandstone aggregate and lightweight aggregate concrete mixtures, respectively. The air-entrained trap rock and limestone mixtures showed porosity increases of 0% and 1.9%, respectively. There was a strong positive correlation between AE cumulative energy and NMR porosity change. XRCT imaging generally showed no frost-induced cracking in the concrete mixtures. Thus, pore structure changes and apparent damage were in the form of microcracks less than the XRCT resolution (22 microns). The results highlight the utility of trap rock aggregate in production of durable concrete for direct LNG containment.

1.0 Introduction

Traditional liquefied natural gas (LNG) tank construction utilizes 9% Ni steel walls and floor for the inner containment tank as it has greater ductility at cryogenic temperatures ($\leq$ -165°C) compared to normal carbon steel. Nevertheless, this construction method is becoming increasingly expensive. However, available literature on concrete properties at cryogenic temperatures shows that most properties of concrete generally improve above their ambient temperature values at cryogenic temperatures [1]. Utilization of concrete for direct LNG containment would lead to huge cost savings. Moreover, the development of the American Concrete Institute (ACI 376-11) standard on concrete structures for containment of refrigerated liquefied gases [2] may increase the impetus for tank designs utilizing concrete for primary LNG containment. Therefore, a thorough understanding of the properties of concrete related to its ability to maintain liquid tightness and structural integrity required for LNG tanks is necessary.

Concrete utilized for direct LNG containment must be dense, durable, nearly impermeable, and resistant to chemicals, with limited deflections and cracking. Its serviceability requirements must include gas-tightness to prevent leakage of LNG vapor and loss of product, and to promote durability [3]. It is evident from the foregoing that the permeability of concrete is of utmost importance in the design of concrete for use in direct LNG containment as it controls the rate by which LNG is lost from the primary container [1]. The permeability of concrete depends on the porosity, pore size distribution, pore roughness, constrictions of the pore space, and the tortuosity and connectivity of the internal pore channels [4, 5]. Moreover, the pore size distribution has a significant influence on the formation of ice and its expansion ability when concrete is cooled to cryogenic temperatures. This in turn affects the development of internal stresses in concrete due to freezing water [1]. One promising technique for quick and reliable determination of pore size distribution and porosity in porous materials like concrete is nuclear magnetic resonance (NMR). Proton NMR (also ^{1}H-NMR) is a fast, potentially non-invasive technique for the characterization of the internal structure of a porous material based on its mobile water molecule content [6]. Similarly, x-ray computed tomography (XRCT) allows for non-destructive 3D visualization of the internal microstructure of materials. XRCT is capable of viewing deeply buried microstructures that 2D surface imaging techniques – e.g. scanning electron microscopy (SEM) – may not observe. Thus, XRCT is a valuable tool used for visualization of internal microcracks and cracks in materials [7]. Furthermore, upon cracking, some of the strain energy of thermally stressed concrete is converted to wave energy, which flows through the material and is eventually released into the air making a sound [8]. This sound can be recorded by appropriately placed acoustic emission (AE) sensors. AE is a well-established, non-destructive technique for damage detection in concrete [9]. It has been successfully deployed for studying frost-induced cracking in rock and concrete [8, 10].

72   A ^{1}H-NMR experiment provides information on the amount of hydrogen in the pore spaces of

73   concrete and is thus a measure of porosity as the porosity can be obtained by comparison of the

74   ^{1}H-NMR signal of concrete with that of an equivalent volume of water. Moreover, NMR

75   relaxation times give information on the pore size distribution of porous media as the decay of

76   the proton (from water molecules) magnetization depends on the length scales of the pores and

77   on the pore-fluid-grain interactions [11]. For instance, it is well known that the transverse

78   relaxation rate $(1/T_2)$ is directly proportional to the surface to volume ratio (S/V) of the pore

79   system. Thus, if the constant of proportionality, ρ_2 – the T_2 surface relaxivity (relaxing strength

80   of the pore surfaces) – is known alongside the T_2 relaxation time, the pore size distribution of a

81   material can be determined. Nevertheless, the presence of paramagnetic ions in concrete

82   components (Portland cement and aggregates) such as Fe^{3+} presents difficulties. Paramagnetic

83   impurities may shorten relaxation times or prevent observation of some of the ^{1}H signal, as well

84   as increase the surface relaxivity of materials [12]. Despite the challenge presented by impurities,

85   NMR relaxometry has been deployed for different applications in cement-based materials. These

86   include hydration kinetics of cement, compressive strength development, the physicochemical

87   characteristics of water molecules according to their confinement level, study of the formation of

88   the microstructure of hydration products, alongside porosity, pore size distribution and pore

89   connectivity within the cement matrix [13-17]. Similarly, XRCT has been successfully deployed

90   for related studies on frozen concrete mortars and cement paste. These include examination of

91   cracking in non-air entrained mortars subjected to 35 freeze-thaw cycles between 25°C and -

92   25°C. The study showed that cracks attempt to follow the weaker interfacial transition zone

93   between sand and cement paste in frost-damaged mortars [18]. XRCT has also been deployed for

94   characterization of the formation and distribution of ice crystals inside and around air voids in

95   air-entrained hydrated cement paste. These investigations revolved around development of air-

96   entrainment admixtures for prevention of frost damage in concrete [19].

97

98   Furthermore, as non-destructive techniques, NMR and XRCT have the advantage of

99   investigating the internal structure of the same specimen before and after environmental changes

100 or mechanical stress. In spite of their enormous advantages, there is a paucity of literature on the

101 aforementioned non-destructive techniques in the study of the microstructure of concrete

102 subjected to cryogenic temperatures, or for evaluating concrete suitability for LNG storage. The

103 majority of previous investigations on concrete behavior for cryogenic applications have focused

104 on mechanical and thermal properties such as compressive and tensile strengths, Young's

105 modulus, creep, coefficient of thermal expansion (CTE) and thermal conductivity [20]. However,

106 Bamforth [21] measured water and gas permeability at cryogenic temperatures using

107 permeability cells, as well as porosity and pore size distribution of frozen concrete using mercury

108 intrusion porosimetry. A similar study in this direction considered the effects of cryogenic

109 temperatures on hydrating white cement pastes using NMR [22]. Albeit, this study mainly
110 investigated pore structure evolution (pore size distribution) as a function of hydration times with
111 a view to understanding cement hydration in the lunar environment.
112
113 The present work sought to evaluate the potential of different concrete mixtures for LNG storage
114 by complementing other assessment techniques with XRCT imaging, NMR and AE
115 measurements of the mixtures. It builds on the findings of a previous related study [8], which
116 showed the utility of AE for studying the potential of frost-induced microcracking in concrete
117 during cryogenic cooling only, in relation to water and chloride permeability testing and XRCT
118 imaging on replicate specimens. However, the present work studied the same concrete specimens
119 before and after cryogenic cooling using NMR and XRCT, while AE measurements were made
120 during the cooling process as well as during warming to ambient temperature. The aim of the
121 study was to relate observed changes in porosity, pore size distribution and internal
122 microstructure to cracking determined from cumulative energy emissions from the materials
123 during the cooling and warming processes. It is thought that even though paramagnetic ions
124 affect NMR relaxation times, changes in relaxation time distributions after cryogenic cooling can
125 be attributed to pore size distribution changes since cooling is unlikely to change the
126 paramagnetic content of a given concrete mixture. It was the object of the study to investigate the
127 potential of the different aggregates to produce frost-damage-resistant concrete.
128
129 **2. Materials and methods**
130 *2.1 Production of concrete specimens*
131 Concrete specimens were produced using river sand as fine aggregate, and coarse aggregates
132 with different CTE values, namely, limestone, sandstone, trap rock and TXI Streetman expanded
133 shale lightweight aggregate. All aggregates were obtained from quarries in Texas, USA. Key
134 physical properties and mineralogical composition of the aggregates have been detailed
135 elsewhere [8]. Type I portland cement was used for casting of all concrete specimens. Table 1
136 shows the composition, mixture proportions and selected properties of the six concrete mixtures
137 studied. Four of the six concrete mixtures were without air-entrainment, while two mixtures were
138 air-entrained with 6% air content. Cubes (150 mm) of the non-air-entrained mixtures produced
139 with ≤ 12.5 mm aggregates were initially tested after 28 and 56 days of water curing. The
140 findings of the AE measurements, XRCT imaging and water and chloride permeability carried
141 out have been reported elsewhere [8]. Thus, the air-entrained mixtures were produced with only
142 limestone and trap rock aggregates, using Master Air AE 200 air-entraining admixture (*BASF*,
143 Ohio, USA), based on the findings of the initial experiments. The grain size distributions of the
144 aggregates used here are shown in Figure 1. The non-air-entrained mixtures had a water/cement
145 (w/c) mass ratio of 0.42, while a w/c ratio of 0.35 was used for the air-entrained mixtures.

146 **Table 1. Composition, mixture proportion and selected properties of the concrete mixtures**

Constituent/property	Limestone mixture	Sandstone mixture	Trap rock mixture	Lightweight mixture	Air-entrained mixture	
					Limestone	Trap rock
Cement (kg/m^3)	512	512	512	512	543	543
Coarse aggregate (kg/m^3)	868	889	1056	661	868	1056
Fine aggregate (kg/m^3)	694	687	670	550	614	591
Water (kg/m^3)	215	215	215	215	188	188
Master Air AE 200 (kg/m^3)	-	-	-	-	2.9	2.4
Bulk density (kg/m^3)*	2460	2370	2650	2040	2415	2615
Compressive strength (MPa)*	36	37	40	36	29	31
% Fe$_2$O$_3$ in coarse aggregate$^+$	0.05	2.40	2.47	5.54	-	-

147 *Value at 28 days curing age; % Fe$_2$O$_3$ in fine aggregate$^+$ = 0.84; $^+$determined through x-ray fluorescence;
148 % Fe$_2$O$_3$ in cement = 2.92% (product information from Qatar National Cement Company).
149
150
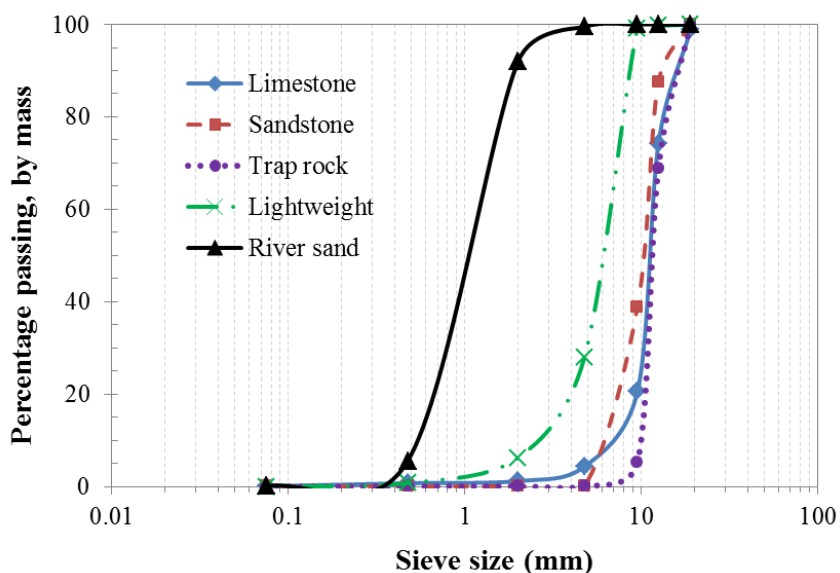

151
152 **Figure 1. Grain size distribution of the coarse and fine aggregates.**

153
154 The exact dimensions of the concrete specimens used were 75 mm diameter by 150 mm long for
155 molded cylinders, and 23 mm diameter by 50 mm long for cores drilled from replicate 150 mm
156 cubes for each mixture. The non-air-entrained and air-entrained specimens were cured under
157 water for 365 and 28 days, respectively, before testing. The non-air-entrained specimens were all
158 casted at the same time while the air-entrained specimens were casted 11 months later. Hence, as
159 the difference in curing age might have some influence on experimental results, the non-air-
160 entrained mixtures should only be compared qualitatively with the air-entrained mixtures. The
161 28-day compressive strengths (tested on cylinders according to ASTM C39 [23] as
162 recommended by ACI code 376 [2]) of the non-air-entrained samples were > 34.5 MPa, while

163 those of the air entrained samples were > 27.6 MPa (Table 1). The strength values correspond to
164 the minimum specified for concrete for refrigerated liquefied gases, when containing liquids
165 (34.5 MPa), and for other reinforced concrete (27.6 MPa) in the relevant ACI code [2].

(a)   (b)

(c)   (d)
Figure 2. Experimental set-up showing arrangement of (a) & (b) thermocouples and AE
sensors, and (c) & (d) temperature chamber with data acquisition system and LN2 dewar.

2.2 Cooling and warming of concrete specimens

The moist concrete specimens were placed in a *Cincinnati Sub Zero* temperature chamber and
cooled from ambient to cryogenic temperatures by liquid nitrogen (LN2) injection (Figure 2).
The temperature chamber is equipped with an inbuilt fan for air circulation inside the chamber.
The highest possible cooling rate the temperature chamber can easily accommodate (3°C/min)
was used to encourage microcracking and to better differentiate the performance of the concrete
mixtures [8]. The temperature chamber was programmed to cool at the aforementioned rate
down to its lowest temperature capacity (-180°C) with a guaranteed soak at that temperature until
the temperature of all concrete specimens were ≤ -165°C. The temperature of the concrete

6

185 specimens was measured and monitored by Type T thermocouples, placed at a surface of the
186 concrete polished with grade 120 abrasive paper (exposing the smaller aggregates), and also
187 inserted into the concrete through drilled holes (Figure 2a). The thermocouples were connected
188 to a data logger, all from *Onset Computer Corporation*, Massachusetts, USA. Thereafter, the
189 cooling program was turned off and a single set point of ~21°C was used to warm the concrete
190 specimens back to ambient temperature. The warming process was not programmed at a certain
191 rate as the study focused on cryogenic cooling, since in practice, most LNG storage tanks do not
192 undergo thermal cycling [1, 20]. This is in contrast to the procedure employed in Kogbara et al.
193 [8], who studied the behavior of some of the mixtures here during cryogenic cooling, wherein the
194 temperature chamber was simply cooled to -165°C. Upon warming to ambient temperature,
195 concrete specimens for NMR measurements were re-saturated, while those for XRCT imaging
196 were air-dried prior to imaging.
197
198 2.3 *NMR measurements*
199 NMR measurements were carried out on two replicate 23 mm diameter concrete cores for each
200 of the concrete mixtures, before and after cryogenic cooling. The measurements were performed
201 with a 2 MHz rock core analyzer using a 54 mm probe (Magritek, Wellington, New Zealand).
202 The NMR system uses a heater to keep the magnet temperature at 30°C for field stability.
203
204 2.3.1 *Determination of porosity and pore size distribution*
205 The NMR instrument measures the volume of pores in a saturated cylindrical core, which in
206 combination with bulk volume measurement of the core and a known volume of the saturation
207 fluid, is used to calculate porosity. In an NMR experiment, a saturated sample is placed in a
208 magnetic field; it is then excited with a series of radio frequency (RF) pulses. After each RF
209 pulse, a small RF signal or echo is generated by the nuclei within the fluid, which is recorded as
210 a train of echoes with a defined spacing, known as the echo time. The signal amplitude that
211 makes up the echo train decays away with one or more relaxation times (T_2) that are
212 characteristic of the fluid and its environment. The initial amplitude of the echo signal indicates
213 the total amount of fluid in the sample. The relaxation time distribution gives information about
214 the environment of the fluid, such as the pore size distribution in the sample [24].
215
216 A water-saturated concrete core covered with plastic cling wrap (to prevent moisture loss) was
217 measured using the NMR instrument calibrated with 20 ml of tap water and correction for
218 background signal. The bulk water T_2 was found to be ~ 3,000 ms. The Carr-Purcell-Meiboom-
219 Gill (CPMG) sequence was used to measure T_2, with 100 μs echo time, inter-experimental delay
220 time of 6,500 ms and 200 scans. The CPMG decay was analyzed with a Lawson and Hanson
221 non-negative least square fit method using Prospa software (Magritek, New Zealand). A suitable

222 smoothing parameter was chosen, which gives a chi-squared close to the ideal value specified by
223 the data, and prevents misplaced residual and data-noise statistics curves, and oscillations in the
224 residuals curve. The software then outputs in excel format the cumulative porosity of the sample
225 alongside the T_2 distribution. The logarithmic mean of the T_2 distribution, which represents the
226 mean pore size, was used for comparison of average pore sizes before and after cryogenic
227 cooling according to the equation
228

$$ T_{2LM} = 10^{(\log_e T_2)} = 10^{\left(\dfrac{\sum_{i=1}^{n} a_i \log_e T_{2i}}{\sum_{i=1}^{n} a_i} \right)}, \quad (1) $$

229

230

231 where, T_{2LM} is the logarithmic mean T_2, T_{2i} and a_i are the relaxation times and intensities,
232 respectively, in the relaxation time distribution.
233

234 2.3.2 *Estimation of surface relaxivity*
235 As mentioned previously, the surface relaxivity (ρ) is required alongside T_2 relaxation time for
236 estimation of pore sizes. The presence of paramagnetic ions in concrete affects accurate
237 determination of the parameter. It is currently unclear whether the presence of paramagnetic ions
238 increases surface relaxivity by the same order of magnitude it decreases relaxation time.
239 Nevertheless, the surface relaxivity of the different concrete mixtures in this work has been
240 estimated in order to provide some idea of the pore sizes in the concrete specimens. Surface
241 relaxivity was determined following the method described by Slijkerman and Hofman [25]. This
242 entailed performing T_2 decay measurements in a fixed gradient field for two different echo
243 times, which allows the extraction of surface relaxivity by modelling the effect of restricted
244 diffusion, using the relation
245

$$ \frac{1}{T_{2D}} = \frac{1}{T_{2S}} + \frac{D_0 \left(1 - \alpha \frac{1}{\rho T_{2S}} \sqrt{D_0 T_e} \right) \gamma^2 G^2 T_e^2}{12}, \quad (2) $$

246

247

248 where, T_{2D} is T_2 decay in a gradient field due to the combined effect of diffusion decay and
249 surface relaxation decay; T_{2S} is the surface relaxation time; D_0 is the bulk diffusion coefficient; α
250 is a constant equal to 0.2223; ρ is the surface relaxivity; T_e is the echo time; γ is the proton
251 gyromagnetic ratio (= 2.675 x 10^8 rad s^{-1}T^{-1}) and G is the sensed field gradient.
252

253 T_2 decay measurements were performed on the concrete cores in a gradient of 34 G/cm (i.e. 0.34
254 T/m) at echo times of 0.5 and 2 ms at 2 MHz. The water diffusion coefficient was determined in

255 a separate NMR diffusion (pulsed gradient spin echo – PGSE) experiment as 2.73 x 10^{-9} m^2/s.
256 The logarithmic mean T_{2D} at both echo times determined above was used in Equation (2). The
257 surface relaxivity was then determined from the solution of the resulting simultaneous equations.
258 The measurements were also carried out on sandstone and river sand samples as a check for the
259 method since the surface relaxivity of both materials have been documented in several works
260 [26-28].
261
262 2.4 *AE monitoring of concrete specimens*
263 A Vallen AMSY-6 multichannel AE measurement system (Vallen System GMBH, Germany)
264 was employed for monitoring of damage accumulation events (hits) during cooling and warming
265 of the concrete specimens. The AE acquisition device is equipped with two AEP4 preamplifiers
266 with a gain of 34 dB and a frequency range of 25–850 kHz. Pancom P15 sensors were coupled to
267 the top of two 75 mm diameter cylindrical concrete specimens from different mixtures using a
268 high vacuum sealing compound, HIVAC-G (*Shin Etsu*, Japan), in a given cooling and warming
269 run. These provided AE hits to the preamplifiers. One sensor was used for each specimen (Figure
270 2b). The sensors are specially designed for composite applications. The resonant frequency is
271 150 kHz and the case material is stainless steel. It has been shown that several commercially
272 available sensors with similar characteristics are rugged enough and have sufficient fidelity to be
273 used in a cryogenic environment [29]. The detailed procedure for the AE data acquisition and
274 post-processing of acquired data is documented elsewhere [8].
275
276 2.5 *Microstructural examination*
277 The internal microstructure of the same 23 mm diameter by 50 mm long concrete core from each
278 of the six mixtures was observed before and after cryogenic cooling using a MicroXCT-400
279 equipment (*Carl Zeiss Microscopy, GmbH,* Jena, Germany). The concrete cores used here were
280 replicates of those used in the NMR measurements. During the CT scanning, a maximum
281 electron acceleration energy of 140 kV was used with a HE #1 filter and the system acquired
282 2,500 projection images in approximately 2 hours 15 minutes. A Macro-70 (0.4X) detector was
283 used, the detector-rotating axis (RA) distance was 28.3 mm, while the x-ray source-RA distance
284 was 120 mm. The same procedure was used for all concrete cores. *ImageJ*, a public domain
285 software, was employed for further image processing. During image processing, raw 16-bit CT
286 data were converted to 8-bit gray scale images. The slices of the frozen specimen of a given
287 mixture were then transformed (rotated) to match the corresponding slices of the unfrozen
288 specimen, where necessary. There were no further adjustments to the brightness and contrast of
289 the converted images to avoid distortion of the details captured.
290
291

3. Results and discussion

3.1 NMR results

The T_2 distributions of the different concrete mixtures are shown together with the cumulative porosities in Figure 3 and Figure 4. Table 2 shows the logarithmic mean T_2 of the relaxation time distributions. It also shows the surface relaxivity determined for the different concrete mixtures and the materials used as a check for the method of determination. In the T_2 distributions, areas higher than zero (peaks) represent pores of different sizes. The first and second peaks, which are present in all mixtures, are for the gel and capillary pores, respectively. Peaks beyond the second peak represent larger pores, cracks and very large pores. The air-entrained limestone mixture apparently showed a lower porosity compared to the corresponding non-air-entrained mixture, contrary to the higher porosity associated with air-entrainment. This is because the former did not achieve complete saturation like the latter since entrained air bubbles do not readily become saturated. Further, the rate at which an aggregate can absorb water is inversely proportional to the size of the pores [30]. The former had a much higher mean pore size than the latter (Table 2). The T_2 distributions here are generally similar to those of Diaz-Diaz et al [16], in which the T_2 values of gel pores of portland cement concrete incorporating gravel and river sand with w/c ratios of 0.3 and 0.6 were around 0.1 ms and 0.2 ms, respectively (Figures 3 and 4).

The logarithmic mean T_2 data shows that there was no change in the pore size distribution of the non-air-entrained limestone and trap rock concrete mixtures as well as the air-entrained trap rock mixture (Table 2). However, there were increases in the logarithmic mean T_2 of the non-air-entrained sandstone and lightweight concrete mixtures, and the air-entrained limestone concrete mixture. The increase in logarithmic mean T_2 suggests mean pore size increase by a factor of approximately 1.5 for the sandstone and lightweight mixtures, and 2 for the air-entrained limestone mixture (Table 2). The same trend is also apparent in the cumulative porosity data, in which the trap rock concrete mixtures, with and without air-entrainment, showed no increase in cumulative porosity after cryogenic cooling. There was a 0.3% increase in the cumulative porosity of the non-air-entrained limestone mixture, which is within the error margin. Hence, there was effectively no increase in the logarithmic mean T_2. In contrast, the sandstone and lightweight mixtures indicated 1.4% and 3.3% cumulative porosity increases, respectively. The air-entrained limestone mixture indicated 1.9% increase in porosity (Figures 3b, 3d and 4b). The generation of interconnected pores and pockets of microcracks during cryogenic cooling and warming probably engendered the porosity and mean pore size increases in the sandstone and lightweight mixtures. Sandstone and lightweight aggregates exhibit significant internal moisture movement, which causes disruptive volume changes [31]. On one hand, the expansion force associated with transformation of water into ice during cryogenic cooling could lead to

10

329 generation of larger pores as many smaller pores interconnect. On the other hand, the number of
330 smaller pores increases such that some microcracks exist independently. This is in line with the
331 findings of a recent study on variation of concrete pores during freezing using XRCT [32].

Figure 4. (a) T_2 distribution and (b) cumulative porosity of the air-entrained concrete mixtures before and after cryogenic cooling.

Table 2. Logarithmic mean T_2 and surface relaxivity of the specimens

Specimen	Logarithmic mean T_2 (ms)[*]		Surface relaxivity (µm/s)
	Before cryogenic cooling	After cryogenic cooling	
Limestone concrete	0.1	0.1	4.7
Sandstone concrete	0.1	0.15	4.9
Trap rock concrete	0.2	0.2	4.8
Light weight concrete	0.7	1.0	5.4
AE limestone concrete	0.5	1.0	4.7
AE trap rock concrete	0.2	0.2	4.5
Sandstone	-	-	9.3
River sand	-	-	3.0

*These are for the relaxation-time distributions in Figures 3 and 4;   AE: air-entrained

The above results are consistent with previous investigations in which the non-air-entrained limestone and trap rock mixtures with no effective mean pore size changes showed very little or no increase in water permeability after cryogenic cooling. Whereas, there was significant increase in the permeability of the sandstone and lightweight mixtures, which showed increases in mean pore sizes [8]. Hence, the aforementioned permeability results support the NMR assessment of porosity and mean pore size changes as well as microcracking. Especially, as it has been shown that microcracking can increase the porosity, and hence change permeability of cement-based materials by about one order of magnitude [33]. The relative contribution of the different types and sizes of pores to permeability is beyond the scope of this paper. The poor

12

363   performance of the air-entrained limestone mixture compared to the non-air-entrained mixture is
364   probably due to the unsuitability of the large aggregate sizes used for air-entrained concrete (see
365   Figure 1). This resulted in a lower compressive strength than the recommended 34.5 MPa limit
366   for refrigerated liquefied gas containment [2]. It has been shown that larger aggregates with high
367   porosity and high permeability delay the pore pressure relaxation time, and thus exhibit high
368   stress at the aggregate–matrix interface [34]. This in turn could create microcracks in the matrix
369   shell, where fatigue tensile stress exceeds the fatigue resistance of the matrix. This, in addition to
370   the aforementioned larger pore development mechanism may be responsible for the porosity
371   increase of the air-entrained limestone mixture. Albeit, the air-entrained trap rock mixture with
372   compressive strength lower than the afore-mentioned limit showed good cryogenic frost
373   resistance. This can be explained by the lower total porosity of the air-entrained trap rock
374   mixture compared to the corresponding limestone mixture (Figure 4b). With similar aggregate
375   pore size distribution in concrete, a lower total porosity (or absorption) leads to higher frost
376   resistance as the amount of water expelled from the aggregate into the paste during freezing is
377   limited [30, 34, 35].

378

379   The surface relaxivity of the sandstone and river sand samples (Table 2) used as checks for the
380   method agreed well with values reported in the literature. A number of authors have reported
381   surface relaxivity values of ~ 9 µm/s for sandstone [26, 28] and 3 µm/s for silica sand [27]. The
382   estimated surface relaxivities of the concrete mixtures fell within a narrow range, 4.5 – 5.4 µm/s
383   (Table 2) despite the different iron contents of the aggregates (Table 1). This agrees with Dalas
384   et al. [36], who suggested that the amount of paramagnetic species is not a first-order parameter
385   in determining surface relaxivity. These values are similar to the surface relaxivities of synthetic
386   cement hydrates - calcium silicate hydrate (5.5 µm/s), gypsum (6.2 µm/s) and
387   monocarboaluminate (1.65 µm/s) - reported by Dalas et al. [36]. Thus, the surface relaxivities
388   estimated here are apparently the average of the relaxivities of the cement hydrates and the
389   natural rocks used as aggregates. Therefore, with the surface relaxivity values (Table 2),
390   assuming cylindrical pore geometry, the pore diameter of the different pores can be estimated
391   from Figures 2 and 3 using the relation [37]:

392

393    $$\frac{1}{T_2} = \rho_2 \left(\frac{S}{V}\right)_{pore} = \rho_2 \frac{2\pi r h}{\pi r^2 h} = \rho_2 \frac{2}{r} = \rho_2 \frac{4}{d}, \quad (3)$$

394   where, ρ_2 is the T_2 surface relaxivity; $\left(\frac{S}{V}\right)_{pore}$ is the surface-to-volume ratio of the pore; r, h

395   and d, are the radius, height and diameter of the pore, respectively. For example, using equation
396   (3), the estimated pore diameter of the gel pores of the non-air-entrained limestone concrete with
397   T_2 ~ 0.2 ms and surface relaxivity, 4.7 µm/s is calculated as 3.8 nm. For the same concrete, the

398   capillary pore diameter with $T_2 \sim 2$ ms (Figure 3a) is calculated as 38 nm. These are within the

399   range of values reported for the gel and capillary pore sizes [38, 39]. Similarly, the pore

400   diameters of the largest voids in the unfrozen lightweight and frozen air-entrained limestone

401   mixtures with T_2 values $\sim$ 1400 ms and 760 ms are calculated as 30 microns and 14 microns,

402   respectively (Figures 3a and 4a). Nevertheless, caution should be taken when converting T_2 data

403   to actual pore sizes since the effect of paramagnetic species on the relaxation is not considered

404   and the pore size is calculated for an equivalent cylindrical pore. In fact, it is common practice to

405   use T_2 as proxy for pore size instead of converting it to actual pore size [16].

406

407   *3.1 AE data during cryogenic cooling*

408   Figure 5 shows the temperature of the concrete specimens during cooling and warming, together

409   with the AE cumulative hits and cumulative energy. Figure 6 shows the amplitude of the AE hits

410   for the different concrete mixtures. In Figure 6, the saturation amplitude is 99.9 dB due to the 34

411   dB gain used. Thus, any event greater than 99.9 dB was recorded as 99.9 dB, although the full

412   energy emitted during the event was recorded. The lightweight, air-entrained limestone and

413   sandstone mixtures had the highest number of cumulative hits ranging from ~530,000

414   (sandstone) to 1.1 million (lightweight), while the trap rock (79,000) and limestone (250,000)

415   mixtures had the lowest cumulative hits (Figure 5c). A comparison of Figures 5a, 5b and 5c

416   shows that the cumulative hits in most of the mixtures started showing a steep increase within the

417   temperature range -20°C to -40°C. The cumulative energy and amplitude plots also showed the

418   same trend, with the latter demonstrating increasing concentrations of high (> 70 dB) amplitude

419   values beyond the above temperature range (Figures 5d and 6). The steep increase in cumulative

420   hits progressed until the temperature range -90°C to -120°C, where there was attenuated

421   increase, which continued until cryogenic temperatures were reached. The steep increase in

422   cumulative hits within the -20°C to -90°C temperature range was occasioned by increase in

423   matrix stresses and microcracking due to ice growth. In addition, since the specimens were tested

424   at near saturation, expansion of the moist concrete, which has been reported to occur within the

425   temperature range, -20°C to -60°C due to ice formation in the capillaries would also cause more

426   AE hits [8, 20]. Further, ice-induced microcracking is reported to cease around -90°C [1, 20],

427   which explains the aforementioned attenuated increase in cumulative hits from -90°C to

428   cryogenic temperatures.

429

430   On the other hand, the cumulative energy continued to increase down to cryogenic temperatures

431   before reaching a plateau, for most of the mixtures (Figure 5d). After the attenuated increase as

432   cryogenic temperatures were approached, the cumulative hits and energy of the concrete

433   mixtures further showed a slight increase at the inception of warming to ambient temperature,

434   and reached a plateau thereafter (Figure 5). The same rebound behavior at the inception of

warming is also obvious in the amplitude plots (Figure 6). The lightweight and air-entrained limestone mixtures still indicated significant increase in cumulative hits throughout the warming stage. These mixtures together with the sandstone mixture had higher cumulative energies, ranging from 33 nJ to 290 nJ (Figure 5d). This is in contrast to the other mixtures with lower cumulative energies (7nJ – 16 nJ range), whose hits rate levelled off within the -60°C to -20°C range. This probably explains the relatively higher change in porosity and mean pore size observed in both mixtures in the NMR experiments. Albeit, the increases in cumulative hits during the warming stage did not necessarily correspond to significant increase in cumulative energy since most of such hits had low energy levels.
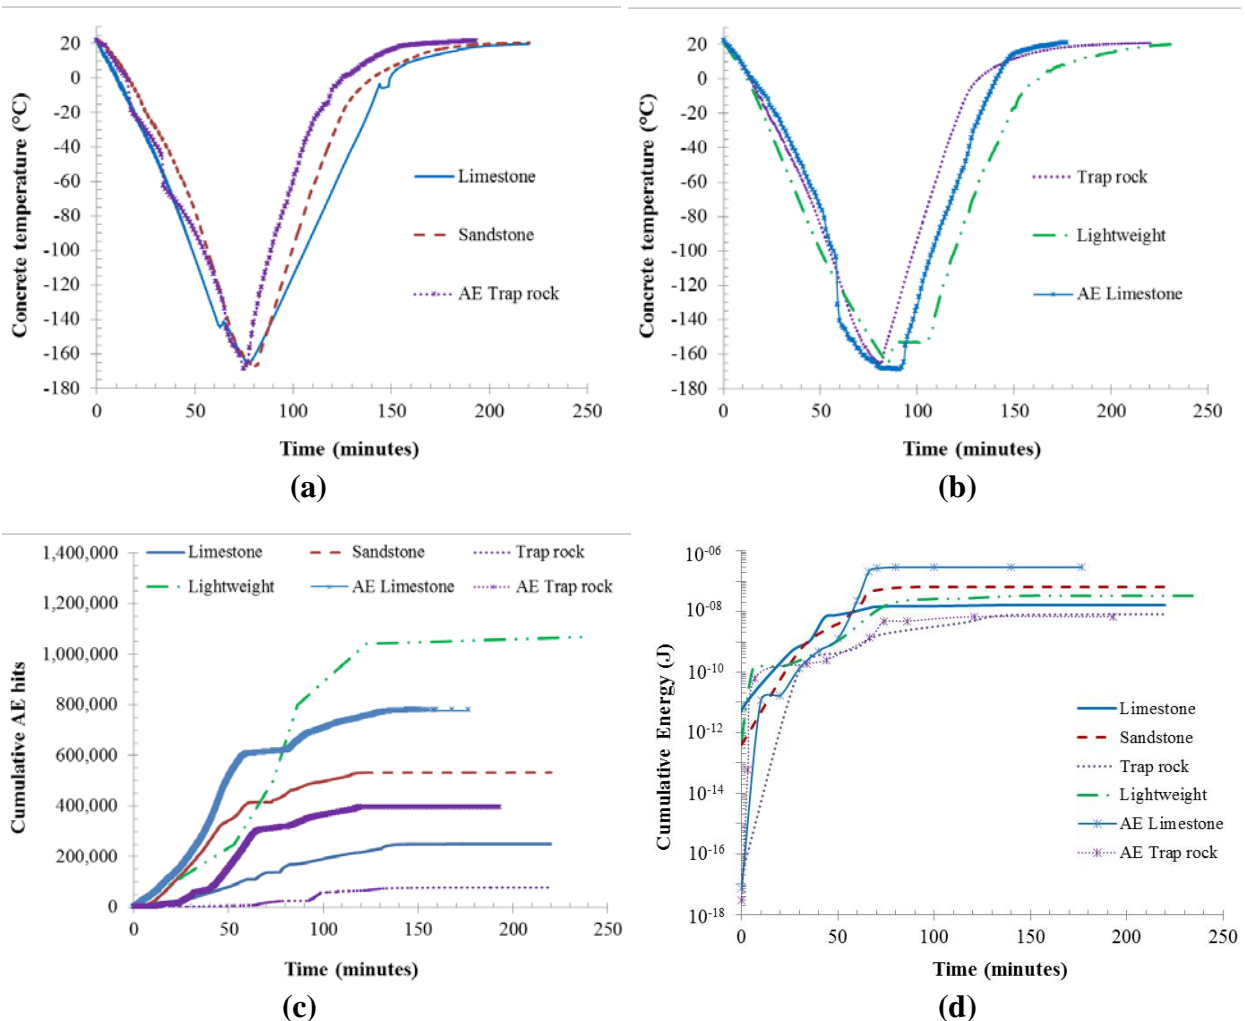

Figure 5. Variation with time of the (a) and (b) temperature (c) cumulative hits, and (d) cumulative energy of the concrete mixtures.

462

Figure 6. Amplitude of AE events from the non-air-entrained (a) limestone (b) sandstone (c) trap rock (d) lightweight, and air-entrained (e) limestone, and (f) trap rock concrete mixtures during cryogenic cooling and warming.

466 The increase in cumulative hits during the warming stage can be attributed to stresses in the
467 concrete due to the differential expansion of ice and concrete. Ice expands faster than concrete
468 during the warming stage due to its higher thermal expansion level. Nevertheless, frozen ice then
469 has sufficient free space for expansion without causing marked microcracking [20]. Thus, AE
470 events during the warming stage may have high amplitudes due to the expansive action of frozen
471 ice, but much lower energy as the expansion is less deleterious to the concrete. This probably
472 explains why the cumulative energy-time curves of the concrete mixtures reach a plateau during
473 the warming stage (beyond ~ 80 minutes), although there were quite a number of high amplitude
474 events from cryogenic temperatures until about -20 to 0°C (~ 80 – 150 mins) (Figures 5d and 6).
475 Further, the leveling-off of the hits rate within the -60°C to -20°C range during warming for the
476 mixes with lower cumulative energies could be linked to the aftermath of the higher expansive
477 action of previously frozen water in pores that takes place within that range [20]. Thereafter, ice
478 changes back to water with an attendant reduction in internal stresses and concrete contraction
479 leading to diminished AE hits rate and amplitude levels. Hence, the AE hit-time curves reach a
480 plateau beyond ~ 150 minutes (Figure 5c).
481
482 Generally, the results in Figures 5 and 6 show that there are more high amplitude AE activities in
483 concrete during cooling to cryogenic temperature than during warming to ambient temperature.
484 Further, it is also evident from the AE results that as concrete approaches cryogenic
485 temperatures, matrix stresses, and hence the tendency for microcracking, declines significantly.
486 This is a welcome behavior for concrete for direct LNG containment since a slower cooling rate
487 as used in the industry would cause far less damage to the concrete during cooling and once at
488 cryogenic temperatures, further damage is unlikely. Moreover, as previously mentioned,
489 historical evidence suggests that most storage tanks are never emptied once filled with LNG,
490 except for tanks at receiving terminals [1, 20] (thus there would be no warming and re-cooling
491 cycles).
492
493 Furthermore, the trend in the AE cumulative hits is very similar to the change in NMR
494 cumulative porosity. The lightweight, air-entrained limestone and sandstone mixtures, which had
495 the highest cumulative hits, also had the highest porosity changes of 3.3%, 1.9% and 1.4%,
496 respectively. Moreover, there was no significant porosity change in the other mixtures with
497 lower cumulative hits. The Spearman's correlation coefficient indicated a very strong positive
498 correlation ($r = 0.90$, $p = 0.015$) between the AE cumulative hits and NMR porosity change. The
499 cumulative energy showed a similar trend, with the mixtures that indicated little or no NMR
500 porosity change emitting the least energies, while those with significant porosity changes emitted
501 more energy (Figures 3, 4 and 5d). There was also a strong positive correlation ($r = 0.81$, $p = 0.05$) between the cumulative energy and NMR porosity change. These show that the association
502 0.05) between the cumulative energy and NMR porosity change. These show that the association
503 between the cumulative hits and energy recorded during cooling and warming of the concrete
504 mixtures, and the resulting porosity change, is statistically significant. Similarly, a strong

505 positive correlation and statistical significance also exists in the association between the mean
506 pore size, as determined from the logarithmic mean T_2, and the cumulative hits, as well as the
507 cumulative energy (r = 0.88, p = 0.02, in both cases) (compare Table 2 and Figure 5).

508

509 *3.2 Microstructural examination*
510 The XRCT images of the concrete mixtures are shown in Figures 7, 8 and 9. The data set
511 consisted of 1014 slices of reconstructed CT images, each with a thickness of ~ 50 microns. The
512 matrix size of the images is 1024 x 1024 pixels with a resolution of 22 microns per pixel in the x-
513 y plane. The rationale behind the millimeter scale of the CT observation is the maximum
514 allowable crack width specified by the ACI 376 code [2]. The code specifies that calculated
515 crack widths within the wall, base slab and roof of the secondary concrete container for
516 refrigerated liquefied gases - there is none for the primary container - shall not exceed 0.012 in.
517 (i.e. ~ 300 micron). A lower value of 0.008 in. (~ 200 micron) was specified within the thermal
518 corner protection embedment zone. These are similar to maximum cracks widths in the order of
519 250 microns reported for cryogenic concrete [38]. In light of the above, a large representative
520 specimen that takes into account the nominal size of the coarse aggregates was employed such
521 that significant cracking within the concrete could be inspected.

522

523 In the slices, with the exception of the lightweight mixture, the aggregates appear as patches with
524 different gray shades, and much brighter than the dark gray shades of the surrounding
525 cementitious matrix. The patches of lightweight aggregates are darker than the surrounding
526 cementitious matrix. Air voids (spherical shapes) and cracks should appear as black or very dark
527 in the images [8]. Five slices are shown for a given concrete mixture, representing the upper,
528 upper middle, middle, lower middle and bottom sections of the core. The slices of a given core
529 shown after freezing are the corresponding, or the closest possible slices to those before freezing
530 in order to facilitate direct comparisons and evaluate the effect of cooling on the cores. This
531 contrasts with the use of replicate cores in a previous related study [8].

532

533 There are no visible cracks due to cryogenic cooling in any of the mixtures (Figures 7, 8 and 9).
534 The only evidence of cracking is in the lightweight mixture (Figure 8). The cracks existed across
535 the coarse aggregate before cooling and there is no clear evidence of them being worsened by
536 cooling. This is in contrast to previous findings based on use of replicate cores [8]. This agrees
537 with the position that the damage (microcracks) formed due to cryogenic cooling is very well
538 distributed, with characteristic crack sizes below the resolution of the CT. Thus, large cracks do
539 not tend to form in the concrete cores, but rather well-dispersed microcracks [8]. It can also be
540 seen from the CT images that the lightweight, sandstone and air-entrained limestone mixtures,
541 which indicated significant NMR porosity changes and higher AE cumulative energies,

apparently had more pockets of large pores in their cementitious matrix compared to the other mixtures. Hence, the presence of such large pores (and cracks for the lightweight mixture) makes concrete more vulnerable to frost damage.
Figure 7. Sample cross-sections of the non-air-entrained limestone and sandstone concrete cores.

The ovals in some of the slices indicate cracks.

556

557   Attempts were made to investigate cracking in the concrete mixtures using SEM imaging in
558   order to support the XRCT observations. This involved collecting micrographs from the same
559   concrete core before and after cryogenic cooling, as well as on frozen cores stored in thermal
560   insulation material, using the low-vacuum mode. Micrographs were also collected from cores
561   subjected to cryogenic cooling, air-dried and gold-coated, in the high vacuum mode. However,
562   the results of the SEM investigations were inconclusive; hence, they are not shown here. This is
563   probably because the cores were not subjected to polishing steps to achieve conditions
564   appropriate for microstructural evaluation as done in recent studies [40, 41]. Nevertheless,
565   concerns abound with regard to the above. On one hand, the application here involves transport
566   of liquid water or dissolved ions at cryogenic temperatures. Hence, evaluation of the still-frozen

567 microstructure is of interest - this precludes the option of polishing, which would cause surface
568 melting due to frictional heat. On the other hand, in examining specimens allowed to thaw,
569 microcracks formed during cooling could close up and the thawed microstructures would not
570 adequately represent the microstructures of the materials in the frozen state.

571

572

573 **4. Conclusions**
574 Three non-destructive techniques, namely, NMR, XRCT and AE were deployed for evaluation
575 of different concrete mixtures. The evaluation sought to identify concrete mixtures capable of
576 resisting damage when cooled to cryogenic temperatures typical of LNG storage tanks. NMR
577 signal intensities indicated cumulative porosity increases of 0%, 0.3%, 1.4% and 3.3% in the
578 non-air-entrained trap rock, limestone, sandstone and lightweight concrete mixtures,

579 respectively. While there were porosity increases of 0% and 1.9% in the air-entrained trap rock
580 and limestone mixtures, respectively. These corresponded to cumulative AE hits ranging from
581 ~79,000 to 1.1 million during cryogenic cooling and warming to ambient temperature. The non-
582 air-entrained trap rock mixture had the lowest, while the lightweight mixture had the highest
583 number of hits. Similarly, AE cumulative energy released ranged from 7 nJ – 290 nJ, with the
584 air-entrained trap rock having the least, and the air-entrained limestone having the highest energy
585 emission. There was a strong positive correlation between AE cumulative hits and energy, and
586 NMR porosity change and mean pore size. XRCT imaging did not show any visible cracking due
587 to cryogenic cooling in the concrete mixtures. It is concluded from the above observations that
588 the generation of interconnected pores and pockets of microcracks during cryogenic cooling and
589 warming occasioned porosity increases in the affected concrete mixtures. Such changes to the
590 pore structure and apparent damage were in the form of microcracks less than the CT's
591 resolution (22 microns).
592
593 The above results corroborate previous data on water permeability of the non-air-entrained
594 concrete mixtures. They suggest that the ability of a concrete mixture to resist frost-induced
595 microcracking goes beyond the aggregate CTE and is mainly an interplay between the aggregate
596 CTE, total porosity and pore size distribution. The inferior damage resistance of the air-entrained
597 limestone mixture compared to the corresponding non-air-entrained mixture suggests the
598 importance of the recommended compressive strength of 34.5 MPa in the design of concrete for
599 LNG storage tanks. The compressive strength (29 MPa) of the former was less than the afore-
600 mentioned value. Albeit, this was not a problem in the air-entrained trap rock mixture with 31
601 MPa compressive strength. These results suggest that trap rock is a highly durable aggregate for
602 the production of concrete for direct LNG containment as it resists frost damage, with or without
603 air-entrainment. Similarly, with the right mixture design, limestone aggregate can also serve as a
604 competing alternative in production of durable concrete for direct LNG containment.
