Abstract

Mitochondrial genomes are readily sequenced with recent technology and thus evolutionary lineages can be sampled more densely. This permits better phylogenetic estimates and assessment of potential biases resulting from heterogeneity in nucleotide composition and rate of change. We gathered 245 mitochondrial sequences for the Coleoptera representing all 4 suborders, 15 superfamilies of Polyphaga, and altogether 97 families, including 159 newly sequenced full or partial mitogenomes. Compositional heterogeneity greatly affected 3rd codon positions, and to a lesser extent the 1st and 2nd positions, even after RY coding. Heterogeneity also affected the encoded protein sequence, in particular in the nad2, nad4, nad5 and nad6 genes. Credible tree topologies were obtained with the nhPhyML (‘non-homogeneous’) algorithm implementing a model for branch-specific equilibrium frequencies. Likelihood searches using RAxML were improved by data partitioning by gene and codon position. Finally, the PhyloBayes software, which allows different substitution processes for amino acid replacement at various sites, produced a tree that best matched known higher-level taxa and defined basal relationships in Coleoptera. After rooting with Neuropterida outgroups, suborder relationships were resolved as (Polyphaga (Myxophaga (Archostemata + Adephaga))). The infraorder relationships in Polyphaga were (Scirtiformia (Elateriformia (Staphyliniformia + Scarabaeiformia) (Bostrichiformia (Cucujiformia)))). Polyphagan superfamilies were recovered as monophyla except Staphylinoidea (paraphyletic for Scarabaeiformia) and Cucujoidea, which can no longer be considered a valid taxon. The study shows that, whilst compositional heterogeneity is not universal, it cannot be eliminated for some mitochondrial genes, but dense taxon sampling and the use of appropriate Bayesian analyses can still produce robust phylogenetic trees.

Key words: Mitogenomes, long-range PCR, rogue taxa, RY coding, mixture models, PhyloBayes
Introduction

Mitochondrial genomes have often been perceived as unreliable phylogenetic markers due to poor recovery of the expected relationships, in particular in early studies that were compromised by sparse taxon sampling (Bernt et al. 2013; Simon and Hadrys 2013). In insects, high rates of nucleotide change in mitochondrial genomes, together with high AT content and constraints of protein function, limit the type of character variation and result in high levels of homoplasy (Talavera and Vila 2011). As rates of change and nucleotide composition vary among lineages, mitogenome sequences are exposed to long-branch attraction, which confounds phylogenetic inferences. This phenomenon has received particular attention in studies of Coleoptera (beetles) showing that compositional heterogeneity is pervasive (Bernt et al. 2013; Cameron 2014; Pons et al. 2010; Sheffield et al. 2009; Song et al. 2010). However, whereas various likelihood models of DNA evolution assume stationarity, i.e. an evolutionary process that keeps the character state distribution uniform across lineages, recent non-homogeneous models accommodate changes in composition over the tree (Boussau and Gouy 2006; Foster 2004; Foster et al. 2009; Galtier and Gouy 1998).

An alternative approach for accommodating complex character variation is the site-heterogeneous CAT model implemented in PhyloBayes (Lartillot et al. 2009), which infers an infinite number of substitution processes (classes) from the empirical data, each of which defined by different equilibrium frequencies of nucleotides or amino acids. This ‘heterogeneous mixture model’ is widely used for the analysis of protein sequences, and was shown to reduce the susceptibility to long-branch attraction (Lartillot et al. 2007; Li et al. 2015; Talavera and Vila 2011). When applied to the Coleoptera, the use of PhyloBayes greatly improved the tree to match expected taxonomic groups over other models applied to the nucleotide sequences. For example, in the analysis of Timmermans et al. (2010) the single representative of the suborder Archostemata (genus *Tetraphalerus*) was placed incorrectly in a derived position within the suborder Polyphaga under various coding schemes and optimality criteria, as also observed in other studies (Pons et al. 2010; Song et al. 2010), but under the CAT model it was placed correctly outside of Polyphaga. Likewise, the CAT model was more successful than other approaches in recovering the major clades including the infraorders (‘series’) within the Polyphaga (Timmermans et al. 2010). To some extent the effect of these mixture models can be achieved by
partitioning the data according to \textit{a priori} determined character sets and applying an independent GTR model, which can be implemented using the RAxML likelihood method (Stamatakis 2006).

The misleading signal from compositional heterogeneity is not produced by all nucleotides in equal measure, as rates are constrained in 1\textsuperscript{st} and 2\textsuperscript{nd} codon positions, which prevents rapid divergence in base composition (Song et al. 2010; Talavera and Vila 2011). Many previous studies therefore excluded 3\textsuperscript{rd} positions from the analysis to reduce the effects of compositional heterogeneity. In addition, RY coding can be used, which removes the AT vs. GC compositional information in the assessment of character variation (Hassanin 2006). Finally, compositional heterogeneity has sometimes been shown to be concentrated in particular portions of the mitochondrial genome or in particular species or subclades, and hence data exclusion has been recommended, e.g. omitting individual genes that produce trees in conflict with the topology obtained from the full data (Talavera and Vila 2011). However, the link between topological incongruence among data partitions and compositional heterogeneity has not been widely explored. In Coleoptera, substitution rates are well known to differ among mitochondrial genes (Pons et al. 2010; Vogler et al. 2005), but the level of compositional heterogeneity has not been compared among genes.

With the application of high-throughput sequencing (HTS) techniques, the number of mitochondrial genomes available for these analyses is increasing rapidly. The resulting denser taxon sampling may improve the estimation of molecular rates and variation in base composition, and thus result in improvements in estimates of tree topology, in particular through reduced long-branch attraction of convergent character variation. Here we generate a large set of mitochondrial genomes for the Coleoptera to test if the known problems for phylogenetic inference in this group previously ascribed to compositional heterogeneity can be overcome by denser taxon sampling. We also examine if high compositional heterogeneity affecting some terminals weakens the recovery of monophyletic groups and produce erroneous relationships. Not all such groups are expected to be strongly supported, but instead the effect of compositional heterogeneity may mainly reduce levels of support for otherwise well founded groups, and as their placement is ill-defined by the data they may appear as nuisance ‘rogue taxa’ weakening an otherwise well supported topology (Wilkinson 1996). Their removal may reduce the compositional heterogeneity across the data and improve the overall tree topology.
We thus examine the evidence for compositional heterogeneity within and among genes, and test its impact on the topology. However, measuring compositional heterogeneity itself is challenging. A $X^2$ test (implemented in PAUP; Swofford 2002) has been widely used to assess if nucleotide composition in a data matrix is homogeneous, but this test suffers from a high probability of Type-II error (the null hypothesis of homogeneity is false but fails to be rejected) because it does not assume phylogenetic relatedness (Kumar and Gadagkar 2001). As the effects of common ancestry are integral to the test quantity, they should be part of the null distribution as well. Such a null hypothesis can be generated by simulating data on the tree topology and model parameters of the empirical data, and the heterogeneity in the empirical data is then assessed against this distribution from simulations, again using the $X^2$ as a test quantity (Foster 2004). This approach is used here to address how compositional heterogeneity in different partitions of the mitogenome data matrix (e.g. various genes, codon positions, clades) affects the accuracy of the tree. We also examine whether these biases can be overcome by analyses of the translated protein sequences and by removal of certain data partitions or divergent lineages, including potential rogue taxa. We show that densely sampled mitogenomes can provide a well-supported tree for the Coleoptera, even under moderate levels of compositional heterogeneity, and these relationships are best captured by the mixture models in PhyloBayes. The new tree consolidates the phylogenetic conclusions from previous studies and resolves several questionable nodes defining coleopteran superfamily and family level relationships.

**Material and Methods**

**Sampling and laboratory procedures**

Mitogenome sequences were generated from long-range PCR amplicons using the Roche/454 sequencing platform. Specimens were selected for uniform coverage of major lineages of Coleoptera from existing DNA extractions of various age and quality of preservation (Bocak et al. 2014; Hunt and Vogler 2008), in addition to newly collected specimens, resulting in highly variable PCR success that limited the taxon choice (supplementary table S1). Amplification primarily targeted a large cob to cox1 fragment of ~10kb. The remainder of the mitogenome was amplified using primer sites in the cox1 and cob genes, to include the rRNA genes and the control region, but amplification success was lower (supplementary table S2). Primers used
are described in Timmermans et al. (2010).

Sequence reads were assembled using the MIRA or Newbler software as described previously (Haran et al. 2013; Timmermans et al. 2010) and the longest contig obtained with either assembler was retained. tRNA genes were annotated with COVE using beetle specific covariance models (see Timmermans and Vogler 2012). Protein coding gene sequences were annotated using existing Coleoptera mitochondrial genomes as reference in Geneious (http://www.geneious.com/). For the rRNA genes, sequences were extracted from the newly generated and previously published mitogenome sequences, using BLAST searches on a fasta formatted database with methods described in Bocak et al. (2014). The taxonomic classification, voucher ID, GenBank accession numbers, and geographic origin for each specimen are given in supplementary table S1.

Phylogenetic inference
The 13 protein coding genes were aligned with ClustalW using the transAlign wrapper (Bininda-Emonds 2005). The cox1 gene was split into the 5’ ‘barcode’ region (Hebert et al. 2003) and the 3’ region widely used in Coleoptera systematics usually amplified with the Pat and Jerry primers (Simon et al. 1994). This was to account for the fact that the two PCR fragments with different amplification success are confined to the 5’ or 3’ ends for the short and long fragment, respectively. The two rRNA genes were aligned using MAFFT v. 7 (Katoh et al. 2009) under default parameters on the server http://mafft.cbrc.jp/alignment/software/. Protein coding alignments were edited, trimmed and translated with Mesquite v. 2.75 (Maddison and Maddison 2014). The final concatenated matrix consisted of the 13 protein coding genes (14 regions taking into account the split cox1 gene) and two rRNA genes, with a minimum of 9 complete protein-coding genes represented in all taxa. All tree searches and analyses of evolutionary patterns were done without further outgroups, except for one case of a PhyloBayes analysis designed to test the basal branching order in the light of non-Coleoptera outgroups. Mutational saturation was assessed in Dambe5, using a simulation-based analysis of the critical substitution saturation beyond which the correct tree is unlikely to be recovered (Xia 2013).

Different partitioning strategies were compared for the nucleotide data matrix of protein coding genes, by calculating likelihood scores on a fixed topology generated in RAxML (Stamatakis 2006). Twelve partitioning schemes for the protein
coding genes were compared, ranging from unpartitioned to a maximum of 42 partitions (by gene + codon position; with the \textit{cox1} gene as two partitions). Likelihood scores were compared with reference to the complexity of the partitioning schemes using the Akaike Information Criterion (AIC). Bayes Factors and Relative Bayes Factors (RBF) were calculated according to (Castoe et al. 2005).

Phylogenetic trees were generated using ML and Bayesian methods for partitioned and unpartitioned datasets. All RAxML trees were generated at the CIPRES web server, under the GTRCAT model of nucleotide substitution, which approximates a GTR+$\Gamma$ model with a reduced computational cost (Stamatakis 2006). Where relevant, node support was assessed using a rapid bootstrap algorithm implemented in RAxML with 500 replicates.

PhyML (Galtier and Gouy 1998) was run on the ATGC webserver and used a GTR substitution model using 8 rate categories. The gamma shape parameter and the proportion of invariable sites were estimated from the data. To infer relationships under the non-homogeneous model of Galtier and Gouy (1998) nhPhyML was used, again using 8 rate categories. Topology, gamma shape parameter and transition/transversion rates were evaluated, but no final optimization of parameters such as branch lengths was performed (setting: -quick=y). As starting tree for tree searches in PhyML and nhPhyML we used the RAxML tree of the complete, partitioned dataset rooted on the Archostemata. Both analyses used the Nearest Neighbor Interchange algorithm.

Finally, the translated data matrix was subjected to Bayesian analysis with PhyloBayes 3 under the CAT-Poisson model (Lartillot et al. 2009). Two MCMC chains were run after the removal of constant sites from the alignment. This Bayesian analysis was repeated with outgroups included. These outgroups were from three orders of Neuroptera, the presumed sister lineage of Coleoptera, and were obtained from GenBank (Accession numbers: NC_011277, NC_011278, NC_013257, NC_015093, NC_021415, NC_023362, NC_024825, NC_024826). PhyloBayes tree searches were also conducted on the CIPRES web server.

The \texttt{R} package ‘ape’ was used to obtain root-to-tip branch lengths from the RY-coded ML and the Bayesian amino acid trees. Mean values and standard deviations of branch lengths were calculated for each suborder and each of the polyphagan subfamilies.
Compositional heterogeneity

Compositional heterogeneity in data matrices based on the protein coding genes was assessed as described in Foster (2004), using the $X^2$ statistic. Significance was assessed using a null distribution generated by simulations on the ML tree with branch lengths and $\alpha$ value ($\alpha$ of the $\Gamma$ distribution) optimized. If the procedure is performed on the entire matrix, this presumes that there is no among-partition rate variation and that branch lengths for all partitions are the same. Since we used a homogeneous model, these values form a valid null distribution by which to assess the $X^2$ of the original data. RY-coded partitions were analyzed as DNA with RAxML. For simulations of protein sequences, the null distribution for assessing $X^2$ was generated using simulations on the corresponding ML tree and the MtArt+$\Gamma$ model (Abascal et al. 2007). Missing taxa will not contribute to the calculated $X^2$ value for the original data, and therefore the $X^2$ calculations were done without the taxa affected by missing data for a given locus. Assessment of significance was based on tail area probabilities $P_t$, and a value of 0.05 or less was taken to show compositional heterogeneity. We also used the conventional $X^2$ test of compositional heterogeneity for comparison. The analysis of heterogeneity was conducted on the ingroup sequences only.

Identification of ‘rogue taxa’

The RogueNaRok algorithm (Aberer et al. 2013) was used to identify ‘rogue taxa’ (Wilkinson 1996), i.e. those taxa that, if excluded from the tree searches, yield a pruned consensus tree with increased support values. Using a RAxML tree on RY coded data (see Results), two settings were tested, allowing either one taxon (run #1) or two taxa to be pruned simultaneously (run #2). The change of support values was assessed on the tree obtained from the ML tree. To handle the effect of interaction between long branches we ran an analysis with a maximum dropset size of 3.

Results

Mitochondrial genomes of Coleoptera
Full or partial mitochondrial genomes were newly generated for 159 taxa by sequencing LR-PCR fragments. In addition, 86 partial or full mitogenomes from previously published sources were incorporated for a combined data set of 245 terminals. The small PCR fragment was represented by fewer taxa, and thus nad2, cox1-5’ and the 12S and 16S rRNA (rrnS and rrnL) genes were missing for 148, 142, 169 and 139, respectively, while the remaining set was nearly complete for all taxa (supplementary table S2), and 51 taxa were represented by the complete set of genes. All terminals had a minimum of nine protein-coding fragments (of 14 fragments in total, including two parts of cox1) and the average data completion was 13.1 fragments, with a total sequence length of 6202 to 11717 bp. The aligned supermatrix consisted of 11141 characters for protein-coding genes, and 12271 characters when the two rRNA genes were included. The two supermatrices contained 15.27% and 20.29% missing data, respectively. The sampling covered all four suborders of Coleoptera, 15 superfamilies of Polyphaga (only leaving out the Derodontoidea for which no sequences were available) and a total of 97 families.

We found several gene order rearrangements in addition to those already described by Timmermans and Vogler (2012), which mainly affected the ARNSEF (Ala, Arg, Asn, Ser, Glu, Phe) cluster between the nad3 and nad5 genes. Three species of Chrysomelidae (Exema, Crytocephalus and Pseudocolapsis) had the order of tRNA^{Ala} and tRNA^{Arg} reversed (RANSEF). This state had previously been observed in Peleopoda (Timmermans and Vogler, 2012), which was placed together with the other three suggesting a single origin of this gene order but the tree topology suggests this group to be paraphyletic for Imatidium, Laccoptera and Arescus which apparently reverted to the ancestral state. In addition, the RANSEF gene order was also observed in a subclade of the distantly related melyrid lineage (Cleroidea), represented by four species, while it was also previously reported from Naupactus (Curculionidae) (Song et al., 2010) and other weevil species (Haran et al., 2013; Gillett et al. 2014). A further rearrangement of this tRNA cluster was seen in Cyphonistes (Scarabaeidae: Dynastinae) (ANRSEF). This represents a new state not previously observed in Coleoptera. Finally, the order of the genes for tRNA^{Lys} and tRNA^{Asp} (KD) located between the cox2 and atp6 loci was reversed (DK) in Sphindus (Sphindidae). In addition to these various rearrangements, we observed two anticodon changes, including a GCG to GCU change in the tRNA^{Ala} anticodon, present in all Polyphaga, and a change from CUU to UUU of the tRNA^{Lys} anticodon, present in all
Chrysomeloidea and also two species of Curculionoidea (only one of them represented in the tree) (figure 1).

**Model testing**

Partitioning greatly improved the likelihood scores. The model testing under the AIC identified the most complex partitioning scheme (partitioning by gene and codon) as the most favorable, with highly significant Bayes Factors against all other partitioning schemes (table 1). However, various partitioning schemes contributed in different ways. Based on the ΔAIC, partitioning by forward and reverse strand resulted in a major improvement over the unpartitioned model, and this could be improved only slightly by further partitioning by genes. Separating the genes according to those genes most strongly affected by compositional heterogeneity (see below) had little impact on the AIC score. In contrast, partitioning by codon positions had a strong effect, and this was further improved by partitioning according to coding on the forward and reverse strands, i.e. using 6 partitions. The likelihood score for this partitioning scheme was closest to that from the full partitioning by gene and codon, and according to the RBF, it is the most efficient way of improving the likelihood scores per parameter added to the model. However, based on the Bayes Factor the model distinguishing 42 partitions was still significantly better.

**Tests of compositional heterogeneity**

The conventional $X^2$ test showed that the data are heterogeneous ($P = 0$ that the data are homogeneous). We then asked if heterogeneity is uniform across the data partitions by performing the test separately on each gene partition and codon position. The 3rd codon positions were heterogeneous for all genes (table 2) and also showed significant levels of saturation for about half of the gene partitions (supplementary table S3). Therefore they were not considered further for tests of heterogeneity. In contrast, all 2nd codon position partitions appeared homogeneous by this test. The 1st codon positions failed for some genes, notably *cytb, nad2, nad4, nad5* and *nad6*, but showed compositional homogeneity in the others. When the 1st codon positions were RY-recoded, the dataset as a whole was still heterogeneous ($P = 0$), but heterogeneity was no longer apparent in the 1st codon positions when tested for each gene individually (table 2).

The data were assessed also against data simulated under a homogeneous model.
(Foster 2004), which revealed heterogeneity (P < 0.05) in 2nd codon positions in genes \( \text{nad2, nad4, nad5 and nad6} \), despite appearing homogenous in the conventional \( \chi^2 \) test. The RY-recoded 1st positions remained compositionally homogeneous. However, it could be argued that using a 2-state model would be more valid for analysis of RY coded matrices, rather than calculations with DNA models. We found that this approach detected highly significant levels of heterogeneity in the \( \text{nad2, nad4, nad5 and nad6} \) genes that were already implicated in 2nd position heterogeneity above (table 2). Finally, we conducted the test of heterogeneity on the translated protein sequence. This showed that out of 14 gene partitions, six were heterogeneous (P < 0.05), and eight were not. The highest level of significance was again observed for \( \text{nad2, nad4, nad5 and nad6} \) (table 2).

The RogueNaRok algorithm identified 14 (run #1) and 30 (run #2) taxa as being inconsistently placed when investigating the placement of a single terminal or a set of two terminals, respectively, for a total of 33 rogue taxa (supplementary table S4). Compositional heterogeneity was investigated for a reduced dataset that had these 33 taxa excluded. The results were very similar to those obtained with the full matrix, with heterogeneity in 2nd positions and in the two-state model of RY-recoded 1st position sites limited to \( \text{nad2, nad4, nad5 and nad6} \) partitions (table 2). Rogue taxa instead seemed to be affected by slightly lower data completion, specifically the sequences for the short amplicon coding for \( \text{nad2 and cox1-5'} \), which was missing from 22 or 23 respectively of the 33 rogue taxa. Yet, the average completion of the dataset for rogue taxa was similar to the complete dataset (12.24 vs. 12.40 protein coding loci per taxon; supplementary table S4), and >120 other taxa in the matrix were also lacking the short fragment (supplementary table S2).

**Phylogenetic analysis**

A series of phylogenetic analyses was conducted to assess the effects of non-homogeneity on tree topology. We used three different approaches for tree searches to make use of the available phylogenetic methods, and scored these trees for about 30 nodes defining deep relationships that were expected based on previous work or appeared noteworthy because they differed among the tree searches here (Table 3; supplementary table S4). We used PhyML and nhPhyML for assessing the sensitivity of the topology to the introduction of branch-specific parameters in the ‘non-homogeneous’ model. The tree generated with PhyML was unsatisfactory in many
regards due to the failure of recovering several key groups, including the large suborders Adephaga and Polyphaga, four of the five infraorders, and the superfamilies in the species rich Cucujiformia. We then compared the topology from the nhPhyML model, which adds a separate parameter for the nucleotide composition for each branch. The nhPhyML tree (supplementary figure S1) was greatly improved, including the monophyly of the suborders and all infraorders. However, in the Cucujiformia only the (reciprocal) monophyly of Tenebrionoidea and Lymexyloidea was recovered, whereas paraphyly remained surrounding Chrysomeloidea, Curculionoidea and Cucuoidea.

The RAxML software was used to assess non-homogeneity across the data (not across the tree, as in nhPhyML) implementing independent GTR models for different partitions of the matrix (although without allowing among-partition rate variation that is not implemented in this software). A tree from the unpartitioned data had many of the same undesirable features as the PhyML tree, including the non-monophyly of Adephaga and Polyphaga, although with a better outcome overall including the recovery of three of five infraorders. Partitioning the data according to the 42 codon and gene partitions improved the topology by recovering all four suborders, the five infraorders and most superfamilies, but problems with the recovery of the cucujiform superfamilies were not fully solved. The impact of including and excluding the two rRNA genes was limited (table 3; supplementary table S4). We further used the RAxML algorithm to explore the effects of removing the most compositionally heterogeneous data, first by removal of 3rd codon positions and RY-coding of 1st positions, and in an additional search we also removed the four loci showing the greatest level of heterogeneity. Finally, we used the amino acid translation (on all protein coding genes) (table 3; supplementary table S4). While most of the correctly recovered higher groupings were robust to the specific data treatment, there was a general decrease in power with the removal of data, and none of these analyses performed better than the partitioned analysis of all nucleotides. Notably, the removal of the rate-heterogeneous genes (nad2, nad4, nad5, nad6) resulted in the loss of monophyly of both small suborders, Myxophaga and Archostemata (see supplementary figure S2 for a tree from a matrix RY-recoded for 1st positions and 3rd positions removed). Equally, the amino acid coding resulted in the failure to recover several key groups, including the suborder Polyphaga that was paraphyletic due to the misplaced Tetraphalerus and Priacma (Archostemata). Hence, the RAxML analysis
was not greatly distorted by compositional heterogeneity and instead suffered more from the loss of data when the most heterogeneous positions were removed.

Finally, the CAT model in PhyloBayes also partitions the data, but unlike the RAxML analysis these partitions are not determined \textit{a priori} but are estimated from the data themselves. The resulting tree (Fig. 1) showed most of the features of the trees from the partitioned RAxML analysis, but also recovered the two large superfamilies Curculionoidea and Chrysomeloidea that were otherwise polyphyletic with respect to each other and included portions of Cucujoidea in all other analyses (supplementary table S4). This tree also recovered a different relationship of the four suborders, linking Adephaga with Archostemata and not Myxophaga, and when rooted with the neuropteroid outgroups, the relationships were (Neuropteroid (Polyphaga (Myxophaga (Archostemata + Adephaga))))) consistent with the findings of transcriptome analyses (Misof et al. 2014). Removal of the four heterogeneous \textit{nad} genes did not greatly change the tree topology, although the resolution was reduced, indicating the loss of phylogenetic signal (supplementary table S4). Finally, the Bayesian analysis was run again after removal of rogue taxa, which produced a tree very similar to that based on the complete dataset, with the main improvement simply due to the absence of the inconsistently placed rogue taxa themselves. For example, only after removing several rogue taxa, in particular the divergent sequence for \textit{Sphindus} (Sphididae), the Nitidulid and Cucujid Series of Cucujoidea each resolved as monophyletic and combined they were the sister group to Curculionoidea + Chrysomeloidea (supplementary table S4).

\textit{The branch-length across superfamilies}

Root-to-tip branch lengths were investigated on the RY-coded ML tree (supplementary figure S2) and the Bayesian amino acid tree (supplementary figure S3) for each suborder and polyphagan superfamily (figure 2 and supplementary figure S4). Variation among these groups was very similar for each dataset. The Adephaga and Myxophaga showed substantially shorter branches than the two other suborders Archostemata and Polyphaga. Shorter branches were found in several polyphagan superfamilies, compared to Bostrichiformia and all superfamilies of Cucujiformia, which are sister groups in most analyses and occupy a derived position in the tree. Within some superfamilies branch lengths were highly variable, e.g. the two sequences of Passalidae with extremely long branches, which were responsible for
shifting the average branch length in Scarabaeoidea beyond the rate of other staphyliniform lineages. Similarly high variation in branch lengths was found in Elateroidea due to extremely long branches in *Trixagus* and *Mastinocerus*. Extremely long branches compared to their sister taxa were found additionally in *Melittomma* (Lymexylidae), *Sphindus* (Sphindidae), Cassidinae (Chrysomelidae) and others. In addition, the rogue taxa had a tendency to exhibit faster rates of nucleotide change, with an average branch length higher than for the complete set of taxa (0.86997 vs. 0.73820) and many terminals in the top part of the range of root-to-tip distances, and a generally higher proportion of rogue taxa was found in superfamilies with higher branch-length variability (supplementary table S5).

**Discussion**

This study generated a large number of new mitogenome sequences for the Coleoptera that more than doubles the available sequences and now permits an analysis of molecular evolution at the resolution of the family level. Early studies of Coleoptera using mitochondrial genomes noted the great heterogeneity in nucleotide composition and molecular rate that apparently misled the trees (Pons et al. 2010; Song et al. 2010). The sparse taxon sampling of studies conducted with conventional Sanger sequencing may have exacerbated these problems. If nucleotide heterogeneity is high and localized in the tree, and if similar composition arises convergently, there will be a tendency to create biases that overwhelm the phylogenetic signal. Already denser taxon sampling, the removal of synonymous codon positions, and the use of protein sequences were shown to partly overcome these problems (Timmermans et al. 2010). This is confirmed here for a much greater set of mitogenomes. However, it was not clear if the improved phylogenetic inference is correlated with reduced compositional heterogeneity, and to what degree heterogeneity can be reduced by removal of the most affected bases and by translation to protein sequences that might reduce the compositional bias from different codon usage.

Previous studies have established the distribution of compositional heterogeneity using the disparity index I_D (Song et al. 2010) that is based on the differences in substitution pattern for pairs of sequences deviating from expectations under a process of uniform nucleotide change. This analysis produced a measure of compositional heterogeneity for each terminal relative to other taxa in the dataset and found that the more densely sampled Polyphaga exhibit the lowest cumulative
disparity across all pairwise comparisons, whereas *Tetraphalerus* as the single representative of Archostemata had the highest disparity when summing the I_D values from comparisons with all other taxa (Song et al. 2010). These findings suggest that compositional heterogeneity is increased between distantly related taxa and therefore greater sampling density, as available in the Polyphaga, ameliorates the problem, although residual heterogeneity remains even in very densely sampled mitogenome trees, e.g. in a tree of ~100 taxa in the family Curculionoidea (Gillett et al. 2014).

In the current study, rather than using pairwise comparisons, heterogeneity was assessed for the matrix as a whole, but only after the data were partitioned by gene. This analysis showed that compositional heterogeneity is concentrated in four genes, all of them NADH dehydrogenases. Two of these (*nad4* and *nad5*) are on the reverse strand, while *nad6*, but not *nad2*, is in proximity to these genes, encoded by the forward strand. It is intriguing that these genes did not deviate in their impact on model fit in the partitioning, as splitting them and all others did not greatly improve the likelihood of the model (table 1). This was in contrast to data partitioning by forward and reverse strand that accounted for a large improvement in statistical fit in GTR models (i.e. under compositional homogeneity assumed by the GTR, and hence indicating different evolutionary patterns on either strand unrelated to compositional heterogeneity). While RY-recoding reduced the problem of compositional heterogeneity, it remains strong if applying a two-state model. Equally, the problem of compositional heterogeneity was not removed by using the amino acid sequences. Nucleotide bias has been shown to feed through to the amino acid level, e.g. there is a correlation of AT or GC rich mitogenomes with a prevalence of particular amino acids, which was established mainly in inter-phyla and inter-order comparisons of mitogenomes greatly differing in base composition (Bernt et al. 2013; Foster et al. 1997; Li et al. 2015), and this seems to be confirmed here at a lower hierarchical level. The finding that predominantly the *nad* genes were affected by heterogeneity, which are functionally linked, might suggest that variation on the protein level and possible covariation in the NAD protein complex, drives compositional heterogeneity, rather than some unspecified genomic process driven by strand bias. Evolutionary shifts in mitochondrial genes have been associated with positive selection, e.g. with changes to respiratory function (Tomasco and Lessa 2011), although because compositional heterogeneity in the four affected genes is encountered in all codon positions, other explanations due to gene-wide effects may also apply.
We also tested if exclusion of so-called rogue taxa improves the tree topology for the remaining taxa. There are different reasons for a taxon to be 'rogue', and here we speculated that compositional heterogeneity is a contributing factor, but their removal had virtually no impact on the degree of compositional heterogeneity in the data. It is not clear what causes their inconsistent placement instead, but multiple factors probably contribute. Rogue taxa have a slightly lower representation of the \textit{nad2} and \textit{cox1-5'} markers located on the shorter PCR fragment than the matrix as a whole. Rogue taxa also have a tendency to show higher rates of nucleotide variation, which appears to interfere with stability of their placement on the tree. These factors may affect the strength of the signal through limited data or weak long-branch attraction.

Taken together, the compositional heterogeneity in Coleoptera mitogenomes is moderate and it is spread over the tree somewhat evenly, and therefore heterogeneity \textit{per se} might not have a great impact on the difficulties to recover the correct tree, in particular for those lineages where the true phylogenetic signal is strong. We can see the effect of nucleotide composition alone if we construct a tree based on the composition of each taxon. Therefore we constructed distance matrices based on nucleotide compositions and made neighbor joining trees based on the distance matrices with the bionj algorithm (Gascuel 1997). Using 100 bootstrap replicates, a consensus tree showed hardly any strong (>50%) support for any lineage, and most support was weak at <20% (data not shown). This confirms the idea that the effect of compositional biases on the tree topology is moderate and not localized.

\textit{Heterogeneity and tree topology}

The three major approaches using the PhyML, RAxML and PhyloBayes algorithms are implementations of very different likelihood models and search strategies, whose performance was assessed in the light of information about the level of compositional heterogeneity. As the tree of Coleoptera remains insufficiently known, the quality of different models cannot be tested against a ‘true tree’, but the knowledge on coleopteran phylogeny is now sufficiently good to rely on the recovery of numerous well established monophyletic groups to assess the quality and thus provides guidance on how to select the most defensible topology. In turn, the assessment against those ‘known’ nodes also provides information on the less well-known parts of the tree to establish basal relationships.
Only the nhPhyML analysis provides a means for testing the effect of non-homogeneity explicitly, as it accommodates changing the G+C/A+T ratio at every node in the tree (Galtier and Gouy 1998), although perhaps at the risk of over-parameterization. The algorithm is implemented only for DNA data. Other tree-heterogeneous models are also implemented for protein sequences, such as the ‘non-homogeneous’ nhPhyloBayes, and the NDCH and the NDRH models (node-discrete composition heterogeneity and node-discrete rate heterogeneity, respectively) which allow different compositions and different rate matrices on different branches, implemented in P4 (Foster et al. 2009). However, neither of these can be applied on the scale required here. The improvement obtained from nhPhyML over the homogeneous PhyML model was considerable, indicating the importance of taking into account the non-homogeneity of nucleotide composition across the tree. This approach clearly increases the number of higher taxa recovered, although the tree remains unsatisfactory in some parts. We also conducted a RAxML analysis that only implements the standard GTR model, i.e. does not parameterize tree heterogeneity, but permits partitioning of the data according to genes and codon positions. Data partitioning clearly improved the tree topology, to a similar degree as the use of the non-homogeneous model in nhPhyML. However, there was no improvement after RY coding and removal of 3rd positions, while the removal of the heterogeneous nad genes or the recoding as amino acids caused a deterioration. The only obvious improvement from omitting the 3rd position was the avoidance of long-branch attraction for two lineages in Elateriformia, *Trixagus* and *Mastinocerus*, which are members of distantly related families, yet display very long terminal branches that group them together in the RAxML tree based on all data including 3rd positions, but not in the other analyses. Interestingly, at least with the search strategy applied here, the nhPhyML analysis does not overcome this problem, suggesting the cause of the long-branch attraction is not primarily due to nucleotide heterogeneity of branches. The great rate acceleration in a few isolated taxa is a curious feature of mitogenome evolution of Coleoptera and affects nucleotide and amino acid variation alike (figure 1; supplementary figure S2 and S3). There is concern that taxa affected by this increased rate are misplaced in the tree, in particular if multiple such sequences attract each other, but for the most striking cases the removal of 3rd position suffices to avoid this type of long-branch attraction.

Finally, the CAT model generated the most defensible trees, and although the
method does not address tree heterogeneity explicitly, apparently it is best equipped to
deal with the complex sequence variation in mitogenomes, as it provides greater
flexibility for modeling different classes of sites with independent substitution
processes (Lartillot and Philippe 2004). Due to the size of the dataset we used the
simpler CAT-Poisson model whose estimate of global exchange rates (obtained
empirically from the data) is shared by all sites. Yet, the CAT and CAT-GTR models
are efficient in dealing with long-branch attraction due to their ability to account more
accurately for saturation and thus the greater power for estimating the evolutionary
process (Lartillot et al. 2007). These analyses were conducted only at the level of
protein sequences, but the improvement over other analyses is not due to the use of
protein data per se. These data are also affected by compositional heterogeneity, and
amino acid coding performed with RAxML did not result in any improvement over
the analysis of the nucleotide variation (table 3, Fig. 3). These findings further support
the power of the CAT model, at least at the level of divergence within the Coleoptera,
where saturation may still be limited. An additional conclusion from this analysis was
that the removal of ‘rogue taxa’ does not greatly improve the tree topologies, while
the level of heterogeneity also is not reduced. Rogue taxa were, however, affected by
longer average branches and hence were more prone to long-branch attraction, and
their removal facilitated the recognition of higher taxa whose limits were blurred
otherwise. For example, the sequence for Sphindus consistently interfered with the
recognition of other lineages in Cucujoidea, and the extremely long-branched
Trixagus interfered with relationships in Elateroidea. Both were recognized as rogue
taxa.

Implications for the phylogenetic tree of Coleoptera

The tree topology obtained from mitochondrial genomes adds to the growing
confidence in the principal lineages of Coleoptera attained in the last two decades
(Bouchard et al. 2011; Hunt et al. 2007; Lawrence and Newton 1995; Lawrence et al.
2011; McKenna and Farrell 2009; McKenna et al., 2015). A schematic summary of
basal relationships from various analyses is given in Figure 3. The results confirm the
monophyly of the four beetle suborders; the monophyly of the infraorders within
Polyphaga; the monophyly of most of Crowson’s superfamilies (Crowson 1970); and
the monophyly of most families (where multiple representatives were used). The
study also paints an increasingly clearer picture of the relationships of these groups to
each other, in particular in the species-rich Polyphaga.

Specifically, the PhyloBayes analysis is the first to favor the sister relationship of Polyphaga to the three other suborders based on mitochondrial genes, which is supported by the transcriptome study of Misof et al. (2014). Rooting was critical for this inference; data from ESTs (Hughes et al. 2006) and a smaller set of mitogenomes (Timmermans et al. 2010) included coleopteran ingroup taxa only and were rooted on Archostemata, which was supported by morphological studies (Beutel and Haas 2000; Friedrich et al. 2009) and by the abundance of fossils of this presumed earliest radiation of Coleoptera (Crowson 1960). However, rerooting these trees with Polyphaga produces the same ingroup topology as found here after inclusion of Neuroptera outgroups. All other molecular studies based on mitogenomic analyses to date favored Myxophaga + Adephaga (Pons et al. 2010; Song et al. 2010; Timmermans et al. 2010), which was also supported by the RAxML and PhyML analyses conducted here, and which could easily be explained by the convergent low evolutionary rates in both suborders (Fig. 2; supplementary figure 4). Previous studies combining mitochondrial data with nuclear rRNA genes generally support a yet different topology of Polyphaga + Adephaga (Bocak et al. 2014; Caterino et al. 2002; Hunt et al. 2007). If indeed Polyphaga is the sister to the other suborders, this would reduce the imbalance of species diversity at the basal node of the tree, given that in previous work Archostemata and Myxophaga with less than 100 species each were thought to be the sister of all other Coleoptera and the Polyphaga, respectively.

Within Polyphaga, we confirm the Scirtidae/Clambidae grade as the earliest branching lineages in Polyphaga, as proposed by Hunt et al. (2007) and Lawrence (2001), to form the new series Scirtiformia. The Elateriformia is the sister to all remaining Polyphaga, again in agreement with studies from ESTs (Hughes et al. 2006), although the RAxML (all nucleotides) and nhPhyML analyses group them as sister to Bostrichiformia. Internal relationships of Elateriformia recover the three large groups Buprestoidea, Elateroidea and Dryopoidea (=Byrrhoidea minus Byrrhidae). The latter is defined by a unique rearrangement of tRNA gene order (Timmermans and Vogler 2012), which is confirmed here for all members of this clade, but the position of Byrrhidae (Byrrhoidea) and Dascilloidea remains ambiguous (supplementary table S4). The Staphyliniformia occupying the next node is composed of three major groups (Histeroidea, Hydrophiloidea, Staphylinoidea) and also includes the Scarabaeiformia (Scarabaeoidea), which should no longer be considered at the
rank of an infraorder. The staphylinoid families Leiodidae + Agyrtidae were repeatedly recovered as sister to Histeroidea, which interfered with the expected sister relationship of Histeroidea and Hydrophiloidea (McKenna et al. 2015) recovered only in the PhyML analyses or when excluding the heterogeneous loci in PhyloBayes. Bostrichiformia were split into two clades composed of Anobiidae (Anobiinae) + Ptiniidae and Dermestidae, and were the sister of Cucujiformia (except in some RAxML and nhPhyML).

Cucujiformia, the infraorder encompassing about half of all species of beetles, was always monophyletic and consists of sequential nodes defining major lineages including Cleroidea, Cerylonid series (Cucujoidea), Lymexyloidea + Tenebrionoidea, remaining Cucujoidea, Chrysomeloidea and Curculionoidea. The Tenebrionoidea were found as sister to Lymexyloidea (Bocak et al. 2014; Gunter et al. 2014; Timmermans et al. 2010). The Cucujoidea can no longer be considered a valid taxonomic group (Hunt et al. 2007; Marvaldi et al. 2009). The mitogenomes now confirm that the Cerylonid series (Robertson et al. 2008) is only distantly related to the other cucujoid lineages, which include sets of families referred to as Nitidulid, Erotylid and Cucujid series by Hunt et al. (2007). These groups cluster closely in the tree, either as an unresolved grade at the base of, or as sister to the Curculionoidea + Chrysomeloidea. Only the PhyloBayes analysis recovers the reciprocal monophyly of Curculionoidea + Chrysomeloidea, which were partly interdigitated in all other analyses, but the monophyly of Chrysomeloidea is supported by the unique GCU tRNA^{Lys} anticodon (figure 1).

Conclusion

The possibilities for rapid sequencing of mitochondrial genomes have brought a new perspective to the phylogenetics of Coleoptera. While compositional heterogeneity is pervasive in these datasets, the study joins others (e.g. Li et al. 2015; Talavera and Vila 2011) in suggesting the power of the CAT model that produced highly satisfactory trees. Partitioned likelihood models with the RAxML software were not much worse, but missed a few critical relationships apparently affected by different rates of molecular change. The problem of compositional heterogeneity has been considered to be a major driver of long-branch attraction, and is frequently thought to be reduced by RY coding and removal of 3rd codon positions, or by using the translated protein sequence. Here we show that these strategies cannot remove
compositional heterogeneity completely, and that heterogeneity is not uniformly distributed among the various mitochondrial genes. While removing and recoding of codon or gene partitions may reduce heterogeneity, tree resolution and support are diminished. As it has become possible to sequence mitochondrial genomes very rapidly (Gillett et al. 2014; Tang et al. 2015), the challenge is to have implementations of the Bayesian mixture models that can be used at the much larger scale required for future studies.

Table 1. Likelihood and AIC values under various partitioning schemes. The likelihood of the data under each partitioning scheme was assessed on the fixed topology of a randomized parsimony tree under a GTR+G model, with the number of partitions, free parameters and ln(L) scores used in the calculations given. ΔAIC refers to the decrease in likelihood relative to the most complex model (partitioning by gene and codon). Values for 2*ln ΔBF10 > 10 are usually considered to be highly significant. Relative Bayes Factor (RBF) was calculated according to (Castoe et al. 2005) as 2*ln ΔBF10/Δ parameters, to penalize greater model complexity.

Table 3. Recovery of key nodes and other features in trees obtained from different analyses with RAxML or PhyloBayes (PB), before and after (excl. heterogeneous) removing the composition-heterogeneous markers \( nad_2, nad_4, nad_5, nad_6 \). RAxML trees were obtained with the RY-coded 1\(^{st}\) positions and 3\(^{rd}\) positions removed, or on all data (including the rRNA genes). All PhyloBayes trees were conducted on the amino acid coded matrix. M, monophyletic; P, paraphyletic or polyphyletic; U, unresolved, consistent with monophyly; Y, yes, a feature is present; N, no, a feature is not present. In some cases the groups were recovered but with certain member taxa absent (-) or other taxa included (+), as indicated. Note that \textit{Sphindus} (Sphididae) was disregarded when scoring Nitidulid and Cucujid series. The asterisks mark the trees that are monophyletic for Geadehaga only if \textit{Habrodera} (Cicindelidae) is disregarded.

**Figure Legends**

Figure 1. The tree of Coleoptera based on protein-coding genes obtained with PhyloBayes. Major groups at the level of superfamily and above are labeled, and each superfamily is illustrated with a representative line drawing. Numbers on the branches represent posterior probabilities. Changes in anti-codons of tRNA$^{\text{Lys}}$ (in Chrysomeloidea and in taxon labeled with blue triangle) and tRNA$^{\text{Ala}}$ (in Polyphaga and taxa labeled with orange triangles) and several newly discovered gene order changes are mapped on the tree.

Figure 2. Mean branch length for major groups at suborder and superfamily levels. The corresponding numbers for the amino acid tree are provided in supplementary figure 4.

Figure 3. Schematic representation of the basal relationships from mitogenome sequences. The tree is based on the PhyloBayes analysis of Figure 1, with outgroups removed. Key nodes were scored for nine trees obtained in various analyses described in table 3.
